FIFTY YEAR CANON OF SOLAR ECLIPSES: 1986 - 2035

Table of Contents

INTRODUCTION

The primary purpose of the Fifty Year Canon of Solar Eclipses: 1986 - 2035 is to provide a reference of moderately detailed eclipse predictions and maps for use by the astronomical community. Such a work should be useful in identifying the most favorable eclipse opportunities, taking into account the celestial mechanics and geographic locations which are paramount in addressing the scientific goals, the issue of funding and the logistical problems of organizing an expedition to remote destinations. Special circulars containing detailed eclipse predictions are regularly issued by the Nautical Almanac Office of the U. S. Naval Observatory. Unfortunately, these circulars only become available 6 to 12 months before each event and cannot be of assistance to long range planning. Canon of Solar Eclipses [Meeus, Grosjean and Vanderleen, 1966] covers eclipses over a broad 612 year period from 1898 through 2510. Because of the sheer number of eclipses covered in this work (1448), the details for any one event must be rather brief. For instance, Meeus et al. give only the center line coordinates of each eclipse using a fairly coarse time interval of every 12 minutes. Center line coordinates over shorter time intervals as well as coordinates for the northern and southern limits and detailed maps of each path would be of great value to planners. The Fifty Year Canon contains this information (Sections 3 & 4), thereby filling a void in the published literature on eclipses.

The secondary purpose is to provide a general reference on future eclipses for teachers, students, amateur astronomers and interested laymen. The solar eclipse is unquestionably the most spectacular celestial phenomenon visible to the naked eye. As such, eclipses generate a great deal of interest among the general public and news media. Naturally, questions arise as to where a particular eclipse will be visible from, and when the next eclipse occurs. Unfortunately, there is very little information in print about the visiblity of future eclipses and what appears in the popular literature is often short on accuracy or even incorrect. Furthermore, most references are obscure, not easily accessible and/or out of print. The orthographic maps in the Fifty Year Canon show regions of visibility for both umbral and penumbral eclipses. From these, the time and maximum magnitude of partial phases or totality/annularity can be estimated for any locale. Furthermore, the 200 year eclipse catalog (Section 1) and world maps of every umbral eclipse during this period (Section 2) provide a convenient and useful reference.

ORGANIZATION OF THE CANON

The Fifty Year Canon of Solar Eclipses: 1986 - 2035 is composed of four major sections and two appendices. Section 1 is a catalog which lists the general characteristics of every solar eclipse from 1901 through 2100. Section 2 presents a detailed set of cylindrical projection world maps which show the umbral paths of every solar eclipse from 1901 through 2100. Section 3 gives geodetic path coordinates and local circumstances on the center line for every central eclipse from 1986 through 2035. Finally, section 4 consists of a series of orthographic projection maps which show the regions of visibility of both partial and central phases for every solar eclipse from 1986 through 2035.

Appendix A provides some general background on solar eclipses and covers eclipse geometry, eclipse frequency and recurrence, modern eclipse prediction, geometry of the umbral shadow and time determination. Appendix B is a listing of a very simple Fortran program which can be used to predict the occurrence and general characteristics of solar eclipses. It makes use of many approximations while maintaining a reasonable level of accuracy and reliability. The program is based on algorithms devised by Meeus [1982] and the ample comments should make the program self-explanatory.

A detailed description of each section of the Fifty Year Canon of Solar Eclipses: 1986 - 2035 follows.

SECTION 1 - SOLAR ECLIPSE CATALOG: 1901 - 2100

Section 1 consists of a catalog of the general characteristics at the instant of greatest eclipse for every solar eclipse during the two hundred year interval 1901 to 2100. During the first century, there are 228 eclipses of which 78 are penumbral and 150 are umbral. The second century contains 224 eclipses of which 77 are penumbral and 147 are umbral. However, to appreciate a realistic frequency and type distribution of present eclipses, it's necessary to sample a period commensurate with the 18 year 11 day Saros cycle. The period from 1986 to 2003 contains 39 eclipses of which 13 (33.3%) are penumbral and 26 (66.6%) are umbral. Of these, 12 (30.8%) are annular, 12 (30.8%) are total and the remaining 2 (5.1%) are annular/total. Since the Saros cycle is not static, these figures will change. For example, eclipses in Saros series 124 will change from annular/total to partial in 2004.

Column 1 of the catalog lists the Gregorian Date of each eclipse while column 2 gives the Julian Date. The Julian Date is the number of days elapsed since Greenwich Mean Noon on 1 January 4713 BC. Column 3 gives the Universal Time (hours:minutes:seconds) of greatest eclipse. Greatest eclipse is defined as the instant when the axis of the Moon's shadow passes closest to the Earth's center. Column 4 lists the value for delta T (in seconds) which was used in the calculations. Delta T is the difference between Terrestrial Dynamical Time and Universal Time. For the period 1901 - 1985, the values for delta T were determined from observations. Beyond 1985, the values for delta T were extrapolated and are only approximate since fluctuations in the Earth's rotation rate are unpredictable (See: Appendix A - Time Determination). Column 5 characterizes the nature of the eclipse as follows:

T = Total Eclipse.
A = Annular Eclipse.
A/T = Annular/Total Eclipse.
P = Partial Eclipse.

Additional information about the eclipse is defined as follows:

B = Begin (i.e. - the first eclipse of a new Saros series).
E = End (i.e. - the last eclipse of an old Saros series).
\+ = Central Eclipse with no Northern Limit.
\- = Central Eclipse with no Southern Limit.
* = Non-Central Umbral Eclipse
(i.e. - edge of umbral cone grazes Earth but shadow axis misses).

The next column gives the Saros series to which the eclipse belongs. The Saros series numbers are consistent with those introduced by van den Bergh [1955]. Eclipses belonging to an odd numbered Saros take place at the ascending node of the Moon's orbit (Gamma decreases with each succeeding eclipse), while eclipses of an even numbered Saros take place at the descending node (Gamma increases with each succeeding eclipse). Column 7 lists the value of Gamma, which is defined as the minimum distance of the shadow cone axis from the center of the Earth in units of equatorial radii. This corresponds to the instant of greatest eclipse. The sign of Gamma indicates whether the shadow cone axis passes north (+) or south (-) of the Earth's center. Column 8 gives the maximum magnitude of the eclipse from any point on the Earth's surface at the instant of greatest eclipse. Eclipse magnitude is defined as the fraction of the Sun's diameter obscured by the Moon. For partial eclipses, the magnitude is always less than 1.000. For annular eclipses, the magnitude is also less than 1.000 and is equal to the topocentric ratio of the diameters of the Moon and Sun. The magnitude for total eclipses is always equal to 1.000. Therefore, the magnitude has been replaced with the topocentric ratio of the apparent diameters of the Moon and Sun. The apparent diameter ratio is always greater than or equal to 1.000 for total eclipses.

The geodetic coordinates of the shadow cone axis at the instant of greatest eclipse are listed in the columns 'LATITUDE' and 'LONGITUDE'. These coordinates are given in degrees and minutes to the nearest tenth of a minute. Negative latitudes are South of the Equator and negative longitudes are East of the Greenwich Meridian. Although greatest eclipse differs slightly from the instants of greatest magnitude and greatest duration (for total eclipses), the differences are usually negligible. For central eclipses, these coordinates represent the point where the Sun reaches its greatest obscuration from any location on Earth. For partial eclipses, the shadow axis misses the Earth entirely. Therefore, the point of greatest eclipse lies on the day/night terminator and the Sun appears in the horizon. The next two columns, 'SUN ALT' and 'SUN AZ', give the Sun's altitude and azimuth as seen from the previous coordinates at the instant of greatest eclipse. The width of the path of totality or annularity at that time follows (kilometers). Finally, the duration of the central phase (total or annular) at the instant of greatest eclipse is given in minutes and seconds.

SECTION 2 - WORLD MAPS OF ECLIPSE PATHS: 1901 - 2100

Section 2 presents maps of the path of every umbral eclipse during the two hundred year period 1901 through 2100 (as tabulated in Section 1). The eclipses are broken up into twenty year intervals and every decade is plotted on a set of three cylindrical projection maps of the Earth. Each map is centered on the equator and covers 160° in latitude (80° North to 80° South) and 130° in longitude. The first map of each trio runs from longitude 160° West to 30° West, the second map covers 40° West to 90° East and the third map encompasses 80° East to 150° West (= 210° East). Thus, the entire planet (excluding the extreme polar regions) is covered with a 10° of longitude overlap between each map.

The northern and southern limits of each eclipse path during a twenty year interval are plotted, along with the outline of the umbral shadow at every half hour Universal Time. Furthermore, the point of greatest eclipse is indicated with an '*', usually near the center of each path. Total eclipses are readily distinguished from annular eclipses because their paths are plotted with a heavier pen. The date of each eclipse appears directly above the point of greatest eclipse ('*'). In cases where the '*' appears within two overlapping eclipse paths, its identity can be established by noting that it usually lies midway between the ends of the path.

There are eight non-central eclipses during the two hundred year interval of Section 2. They occur in 1928, 1950, 1957 (two), 1967, 2014 and 2043 (two). These non-central eclipses are easily recognized by their distictive 'D' shaped paths and from the fact that the point of greatest eclipse lies on the terminator edge of the path. In addition, the annular eclipse of May 2003 has no northern limit, while the annular eclipse of Feb 2044 has no southern limit. These two events are also bounded by the terminator along their missing edges.

SECTION 3 - CENTRAL PATH CATALOG: 1986 - 2035

Section 3 consists of a series of tables which list the geodetic coordinates of the path of totality or annularity for every central eclipse over the fifty year interval 1986 to 2035. During this period, a total of 109 solar eclipses occur; 37 are penumbral or partial while the remaining 72 are umbral. Appearing at the top of each table is the type of eclipse (annular, total or annular/total) and date, followed by the Saros series and the extrapolated value of delta T which was used in the calculations. The first column of each table gives the Universal Time (UT) for the data which follows. Depending on the duration of the central eclipse, data are listed at one, two, four or six minute intervals. The next six columns define the geodetic coordinates of the northern and southern limits as well as the center line. The latitude and longitude of each point are given in degrees and minutes to the nearest tenth of a minute. Negative latitudes are South of the Equator and negative longitudes are East of the Greenwich Meridian.

The column identified as 'DIAMETER RATIO', is the ratio of the topocentric apparent diameters of the Moon and the Sun. For total eclipses, the ratio is always greater than or equal to 1.000. For annular eclipses, the ratio is less than 1.000 and is identical to the eclipse magnitude at maximum eclipse. Eclipse magnitude is defined as the fraction of the Sun's diameter obscured by the Moon. The next two columns, 'SUN ALT' and 'SUN AZ', give the Sun's altitude and azimuth at maximum eclipse as seen by an observer on the center line. The eleventh column lists the width of the path of totality or annularity in kilometers. Finally, the duration of the total or annular phase is given in minutes and seconds. For annular/total eclipses, the sections of the path which are total in nature are identified by a 'T' after the duration.

All path characteristics are calculated for sea level and the effects of refraction have been ignored. As we progress into the twenty-first century, the actual value for delta T will inevitably diverge from the extrapolated ones because of the unpredictable fluctuations in the Earth's rotation (See: Appendix A - Time Determination). The result of this divergence will be to induce a shift in the path coordinates east or west in longitude. Fortunately, corrections to the tabulated longitudes are quite straight forward, using the following equation:

$$\text{Shift (in degrees)} = 0.00417807 * (\Delta T1 - \Delta T2)$$

where: $\Delta T1$ = table value of delta T (in seconds)
$\Delta T2$ = true or observed delta T (in seconds)

This shift is added to the tabulated path longitudes to calculate the correct longitudes of the umbral path. Changes in delta T have no effect on the tabulated latitudes.

It should be pointed out that the path of the annular eclipse of 29 April 2014 is not included in this section because it has no central line. The shadow axis misses the Earth while the edge of the shadow cone barely grazes the planet. Furthermore, the annular eclipse of 31 May 2003 has no northern limit since the northern edge of the shadow cone misses the Earth. In this case, the northern boundary of the path is defined by the Earth's day/night terminator.

SECTION 4 - GLOBAL MAPS OF SOLAR ECLIPSES: 1986 - 2035

Section 4 consists of a series 109 maps, one for every solar eclipse during the fifty year interval 1986 to 2035. Each map is an orthographic projection of the Earth which shows the path of partial and central eclipse. North is to the top in all cases and the daylight terminator is plotted for the instant of greatest eclipse. The sub-solar point on the Earth is indicated by a star shaped character. The maps for partial eclipses are oriented with their origins (i.e. - disk center) at the sub-solar longitude at the instant of greatest eclipse and the latitude is equal to the Sun's declination plus or minus 45° (depending on the hemisphere). The maps for total or annular eclipses are oriented with the point of greatest eclipse at the origin.

The limits of the Moon's penumbral shadow delineate the region of visibility of the partial solar eclipse. This irregular or saddle shaped region often covers more than half of the daylight hemisphere of the Earth and consists of several distinct zones or limits. At the northern and/or southern boundaries lie the limits of the penumbra's path. Partial eclipses have only one of these limits, as do central eclipses when the shadow axis falls no closer than about 0.45 radii of the Earth's center. Great loops at the western and eastern extremes of the penumbra's path identify the areas where the eclipse begins/ends at sunrise and sunset, respectively. If the penumbra has both a northern and southern limit, the rising and setting curves form two separate, closed loops. Otherwise, the curves are connected in a distorted figure eight. Bisecting the 'eclipse begins/ends at sunrise and sunset' loops is the curve of maximum eclipse at sunrise (western loop) and sunset (eastern loop). The points 'P1' and 'P4' mark the coordinates where the penumbral shadow first contacts (partial eclipse begins) and last contacts (partial eclipse ends) the Earth's surface. If the penumbral path has both a northern and southern limit, then points 'P2' and 'P3' are also plotted. These correspond to the coordinates where the penumbral shadow cone becomes internally tangent to the Earth's disk.

A curve of maximum eclipse is the locus of all points where the eclipse is at maximum at a given time. Curves of maximum eclipse are plotted at each half hour Universal Time. They generally run from the northern to the southern penumbral limits, or from the maximum eclipse at sunrise and sunset curves to one of the limits. If the eclipse is central, the curves of maximum eclipse run through the half-hourly outlines of the umbral shadow, from which the Universal Time of each curve can be identified. The curves of constant eclipse magnitude

delineate the locus of all points where the magnitude at maximum eclipse is constant. These curves run exclusively between the curves of maximum eclipse at sunrise and sunset. Furthermore, they're parallel to the northern/southern penumbral limits and the umbral paths of central eclipses. In fact the northern and southern limits of the penumbra can be thought of as curves of constant magnitude of 0.0. The adjacent curves are for magnitudes of 0.2, 0.4, 0.6 and 0.8. The northern and southern limits of the umbra which define the path of totality are curves of constant magnitude of 1.0.

Greatest eclipse is defined as the instant when the axis of the Moon's shadow passes closest to the Earth's center. Although greatest eclipse differs slightly from the instants of greatest magnitude and greatest duration (for total eclipses), the differences are usually negligible. The point on the Earth's surface which is at or is nearest to the axis at this time is marked by an '*'. For partial eclipses, the shadow axis misses the Earth entirely. Therefore, the point of greatest eclipse lies on the day/night terminator and the sun appears in the horizon. For central eclipses, the umbral path begins and ends along the curves of maximum eclipse at sunrise and sunset. The outline of the Moon's umbral shadow is plotted at every half hour Universal Time along the central path. In addition, the umbra's position is labeled at each integral hour Universal Time.

Data pertinent to the eclipse appear with each map. In the upper left corner are the Universal Times of greatest eclipse and conjunction of the Moon and Sun in right ascension, the minimum distance of the Moon's shadow axis from the Earth's center in Earth radii (Gamma) and the geocentric ratio of diameters of the Moon and the Sun. For partial eclipses, the geocentric ratio is replaced by the magnitude at greatest eclipse. To the upper right are exterior contact times of the Moon's shadow with the Earth. P1 and P4 are the first and last contacts of the penumbra; they mark the start and end of the partial eclipse. U1 and U4 are the first and last contacts of the umbra; they denote the start and end of the total or annular eclipse. Below each map are the geocentric coordinates of the Sun and Moon at the instant of greatest eclipse. They consist of the right ascension (RA), declination (DEC), apparent semi-diameter (SD) and horizontal parallax (HP). The Saros series for the eclipse is listed, followed by a pair of numbers in parentheses. The first number identifies the sequence order of the eclipse in the series, while the second number is the total number of eclipses in the series. The Julian Date (JD) at greatest eclipse is given, followed by the extrapolated value of delta T (ΔT) used in the calculations (delta

T is the difference between Terrestrial Dynamical Time and Universal Time). Finally, the geodetic coordinates of the point of greatest eclipse are given, as well as the local circumstances there. In particular, the Sun's altitude (ALT) and azimuth (AZ) are listed along with the duration of totality or annularity (minutes:seconds) and the width of the path (kilometers).

ACCURACY OF THE EPHEMERIDES

The solar ephemeris which was used for these predictions is based on the classic work of Newcomb [1895]. It includes all planetary perturbation terms in longitude and latitude with arguments greater than 0.01 arc-seconds. The lunar ephemeris was developed primarily from the the work of Brown [1919] with improvements from Eckert, Jones and Clark [1954]. All solar perturbation terms in longitude and latitude with coefficients greater than 0.025 arc-seconds have been included. The cut-off for planetary perturbations is 0.025 and 0.01 in longitude and latitude respectively. Perturbations in lunar parallax include all terms with coefficients greater than 0.0010. Finally, all terms additive to the Moon's fundamental arguments with coefficients greater than 0.025 arc-seconds have been retained.

In order to determine the accuracy of these ephemerides, they have been compared against the Jet Propulsion Laboratory's Developmental Ephemeris 200 (or JPL DE-200) for 260 new moon dates over the interval 1980 through 2000. The mean differences and standard deviations of the solar and lunar ephemerides with the JPL DE-200 are as follows:

Comparison of Solar/Lunar Ephemerides with JPL DE-200

	RA Mean (sec)	RA S. Dev. (sec)	Dec Mean (arc-sec)	Dec S. Dev. (arc-sec)
Sun	+0.036	0.044	-0.030	0.173
Moon	-0.002	0.031	-0.008	0.386

The solar and lunar deviations in declination correspond to an uncertainty in the umbral shadow's position of 1044 meters in the north/south direction in the Earth's fundamental plane. Similarly, the deviations in right ascension correspond to an uncertainty in the umbra's position of 2102 meters in the east/west direction. The mean angular velocity in right ascension of the Moon with respect to the Sun is 0.0343 seconds per second. Thus, the combined uncertainties in right ascension can also be thought of as an uncertainty of 2.2 seconds in time.

On the scale of the maps presented in Sections 2 and 4, path shifts of this magnitude are not visible. Thus, the uncertainties are well within the acceptable range for the purposes of predicting eclipse path coordinates and local circumstances for long range planning. In fact, the predictions presented here should be adaquate for most center line experiments. However, observers near the path limits will require predictions using higher accuracy ephemerides which also take into account a detailed analysis of the Moon's limb profile. Such information is available through special eclipse circulars published by: Nautical Almanac Office, U. S. Naval Observatory, Washington, D.C. 20392-5100, U.S.A.. These circulars are available 6 to 12 months before each major eclipse. For eclipses of low solar altitude, the observer must also make corrections for the effects of atmospheric refraction.

In the generation of eclipse predictions presented in the Fifty Year Canon, the author has applied a -0.6 arc-second correction to the Moon's ecliptic latitude. This takes into account the difference between the Moon's center of mass and center of figure. In addition, a correction of -1.34 seconds has been applied to the lunar ephemeris to reconcile it with the FK4 equinox.

In August 1982, the IAU General Assembly passed a resolution to adopt a value for the mean lunar radius of k=0.2725076, in units of the Earth's equatorial radius. This is the value currently used by the Nautical Almanac Office for solar eclipse predictions [Fiala and Lukac, 1983] and is believed to be the best mean radius, averaging mountain peaks and low valleys along the Moon's rugged limb. Previously, the Nautical Almanac Office used two separate values for 'k' in their eclipse predictions. The larger value (k=0.2724880) was used for annular eclipses and exterior contacts while a smaller value (k=0.272281) was reserved for second and third contact calculations of total eclipses [Explanatory Supplement, 1974]. In principle, the IAU's adoption of one single value for 'k' is commendable because it should eliminate confusion arising from the use of two different values. It also eliminates the discontinuity present since two different values of 'k' were used for total and annular eclipses. Nevertheless, a smaller value of 'k' is still necessary since it represents the lunar valley bottoms and hence the minimum solid disk. This is significant because a solar eclipse cannot be regarded as total as long as any photospheric rays reach the observer through valleys along the lunar limb [Meeus, Grosjean and Vanderleen, 1966].

Of primary interest to most observers are the times when central eclipse begins and ends (second and third contacts, respectively) and the duration of the central phase. When the IAU's mean value for 'k' is

used to calculate these times, they must be corrected to accommodate low valleys (total) or high mountains (annular) along the Moon's limb. The calculation of these corrections is not trivial but must be performed, especially if one plans to observe near the path limits [Herald, 1983]. For observers near the center line of a total eclipse, the limb corrections can be closely approximated by using a smaller value of 'k' which accounts for the valleys along the profile.

For this reason, the author has chosen to adopt the smaller value for 'k' (k=0.272281). As a consequence, the current work predicts slightly shorter durations and narrower paths for total eclipses when compared with the Nautical Almanac Office's calculations which use the larger IAU value for 'k'. Furthermore, the smaller 'k' will produce longer durations and wider paths for annular eclipses.

The total solar eclipse of 3 October 1986 illustrates the effects of using different values of k in eclipse calculations. For example, the Fifty Year Canon predicts a maximum duration of totality of 0.2 seconds and a path width of 2.3 km (k=0.272281). However, the Astronomical Almanac for 1986 predicts a duration of 3.3 seconds and a path width of 31.1 km (k=0.2725076). Experienced observers in the path reported that the eclipse was never quite total. Instead, Baily's Beads surrounded the Moon for several seconds during maximum eclipse. The symmetry of the beading phenomena in photographs proves that the observers were near the center line and not the edge of the path. Thus, predictions using the smaller 'k' are in better agreement with actual observations made near the center line.

FIFTY YEAR CANON OF SOLAR ECLIPSES : 1986 - 2035

APPENDIX A - SOLAR ECLIPSES

GEOMETRY OF SOLAR ECLIPSES

One of the most remarkable coincidences found in nature is the fact that the Moon and Sun both appear the same size as seen from the Earth. The Moon, a small, cold, dark body, is only 3500 km in diameter while the Sun, a self luminous, gaseous giant, is 1,400,000 km across. The coincidence arises from the fact that although the Sun is 400 times larger than the Moon, it's also 400 times farther from the Earth. A direct consequence of this fortuitous geometry is that during a total solar eclipse, the Moon occults the Sun with a nearly perfect fit.

The fundamental basis of the solar eclipse is the alignment of the Sun, Moon and the Earth such that some region of the Earth passes through the Moon's shadow. This shadow is composed of two parts: the outer or penumbral shadow and the inner or umbral shadow. From within the penumbra, only part of the Sun is obscured. In contrast, the dark, central umbra is the shadow of complete or total eclipse. During a total eclipse, the umbra sweeps across the Earth from west to east and the course it travels is called the path of totality. Anyone standing within this zone will see the Sun completely obscured by the Moon for as long as 7 1/2 minutes. At this time, the solar corona is visible as a halo about the Moon and the landscape takes on the appearance of an eerie twilight. Outside the path of totality but still within the penumbra, a partial eclipse is seen. The path of the umbra is rarely more than 300 km wide while that of the penumbra is about 7000 km wide. Sometimes the umbral shadow misses the Earth entirely and only a partial eclipse occurs.

Eclipse geometry is complicated by the fact that the Earth's orbit around the Sun is elliptical. As a result, the Sun's apparent semi-diameter varies from 944 arc-seconds at aphelion to 976 arc-seconds at perihelion. This 3% range in apparent size is, of course, quite indistinguishable to the naked eye.

However, the orbit of the Moon about the Earth is also elliptical. The Moon is 406,700 km from the Earth's center at apogee and 356,400 km at perigee. This 12% range in distance causes the Moon's apparent semi-diameter to vary between 882 and 1006 arc-seconds. Thus, during a total solar eclipse, the Moon's apparent diameter can exceed the Sun's by as much as 7% or 2 arc-minutes. Conversely, it's also possible for the Moon to appear almost 10% or 3 arc-minutes smaller than the Sun.

Such a geometry results in the case of an annular solar eclipse. When the Moon is near apogee, it's umbral shadow falls short of the

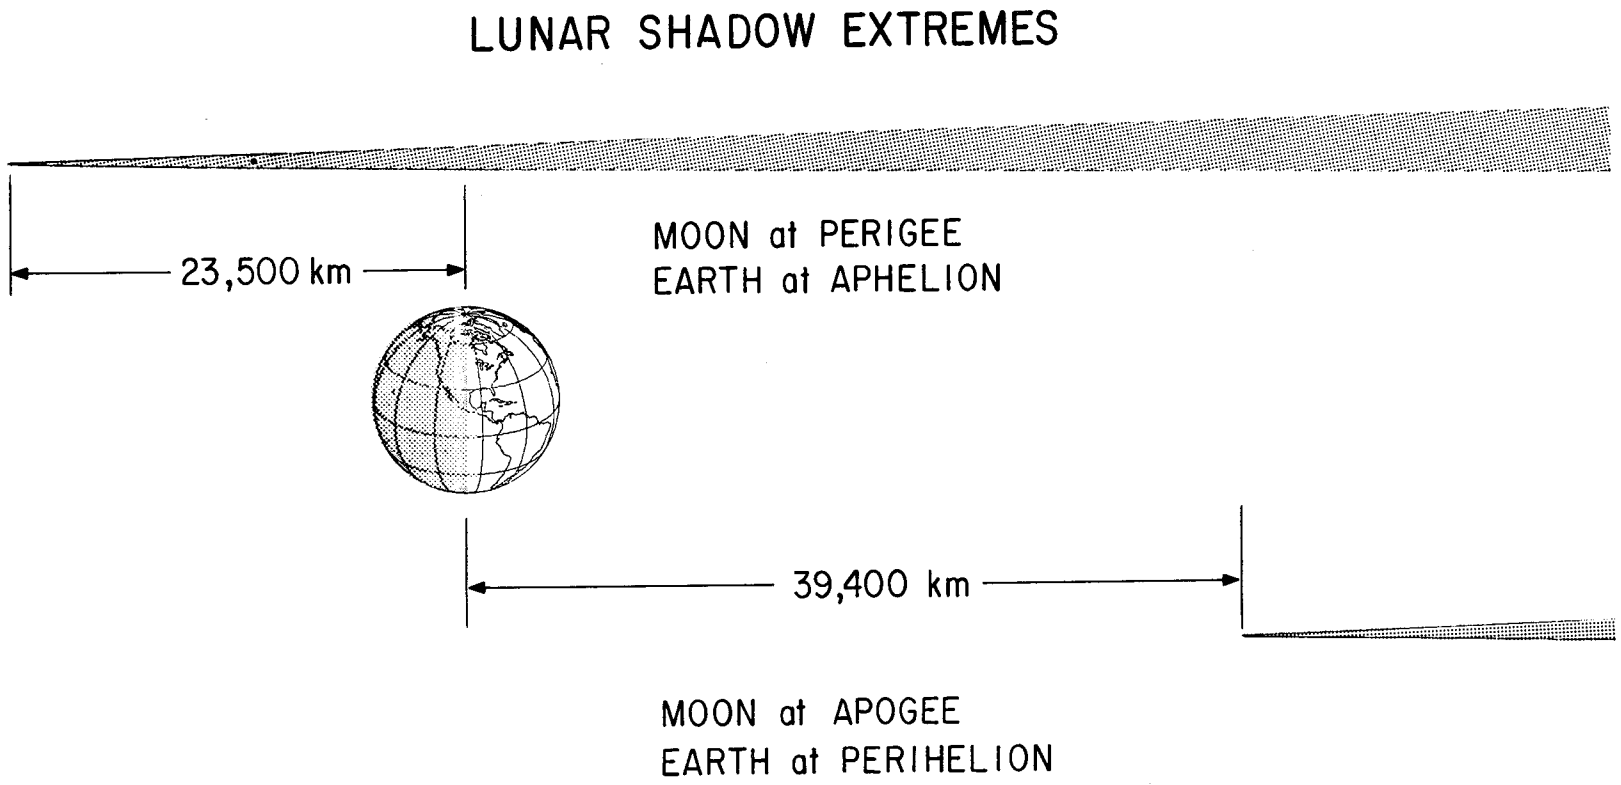
Earth and the Moon appears smaller than the Sun. An observer stationed in the path of totality would see the Moon completely silhouetted against the Sun's bright photosphere. This type of eclipse takes its name from the ring or annulus of sunlight which surrounds the Moon at maximum eclipse. Unfortunately, the blindingly bright photosphere hides the corona from view and precludes any measurements or photographs of the Sun's outer atmosphere.

The term "central eclipse" is reserved for any eclipse in which the axis of the Moon's shadow intersects the Earth. From the previous discussion, it's obvious that a central eclipse can be either total or annular in nature. When the Moon is at perigee and the Earth is at aphelion, the shadow extends 23,500 km beyond the Earth's center. However, when the Moon is at apogee and the Earth is at perihelion, the shadow falls 39,400 km short of the geocenter. These represent the extremes of the Moon's umbra (Figure 1). In the first case, the umbral cone can have a maximum diameter of 273 kilometers at the Earth. If the surface of the shadow cone in the second case is extended, it generates a negative or anti-umbra. As it strikes the Earth, the anti-umbra can have a maximum diameter of 313 km and an observer positioned there will see an annular eclipse.

A third type of central eclipse is possible which forms the transition between the annular and total eclipse. It occurs when the umbral shadow is just long enough to reach part of the Earth's surface, but not the Earth's center. In this case, the eclipse will be annular at either end of the eclipse path while it will be total along the middle section. The eclipses of 3 October 1986 and 30 March 1987 are two examples of the annular/total eclipse.

ECLIPSE FREQUENCY AND RECURRANCE

Having established the preliminary geometry for solar eclipses, a question immediately arises. Why doesn't a solar eclipse occur at every new Moon? Since the Moon cycles through its phases every 29 1/2 days or one synodic month, one would expect an eclipse to occur during each conjunction with the Sun. If the Moon's orbit around the Earth were in the same plane as the Earth's around the Sun, this is precisely what would happen. However, the Moon's orbit is inclined 5° to the Earth's. Our planet's natural satellite passes through the ecliptic only twice a month at a pair of points called the nodes (Figure 2). The rest of the time, the Moon is either above or below the plane of the Earth's orbit. Since an eclipse can only occur when the Sun, Moon and Earth lie in



LUNAR SHADOW EXTREMES
23,500 km
MOON at PERIGEE
EARTH at APHELION
39,400 km
MOON at APOGEE
EARTH at PERIHELION

Figure 1

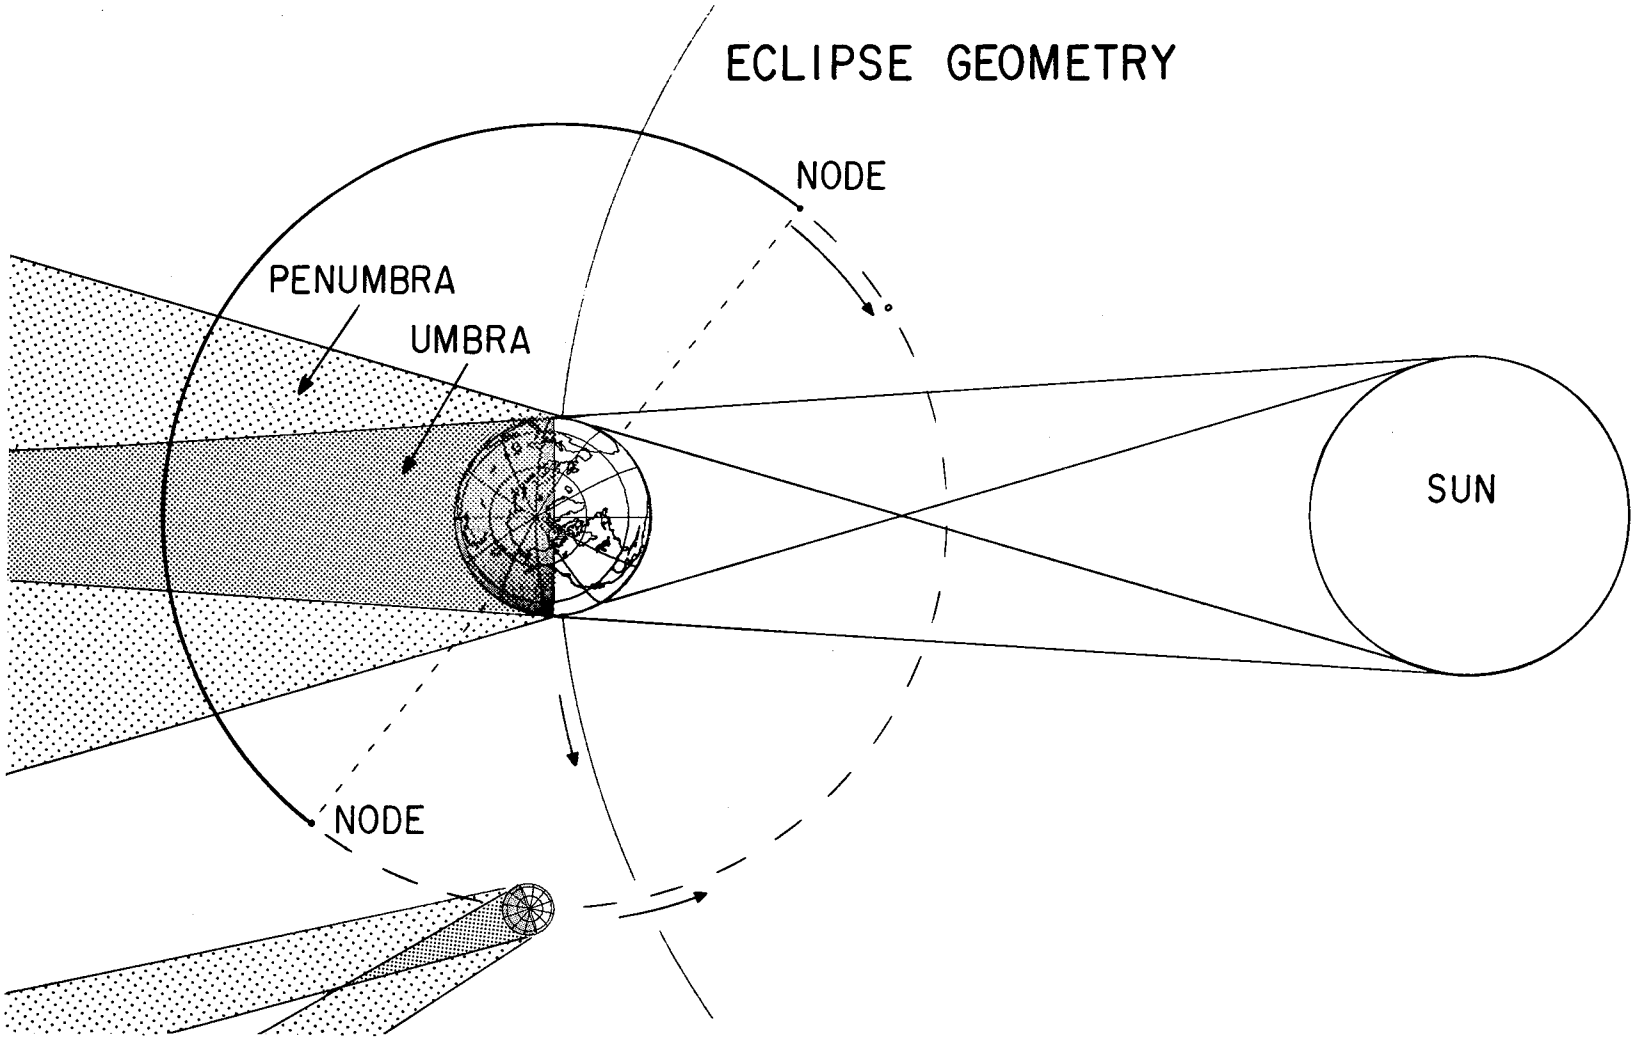


Figure 2

the same plane, these conditions are met when new Moon takes place at one of the nodes.

Contrary to popular belief, solar eclipses are not at all rare. In fact, they're more common than lunar eclipses. An examination of the exterior tangents which delineate the Earth's umbra will substantiate this claim. An eclipse is possible only when the Moon is within that section of its orbit inscribed by the exterior tangents. However, the sunward arc of the Moon's orbit is clearly longer than the anti-sunward arc which passes through the shadow. The number of solar and lunar eclipses that occur are proportional to the lengths of these two arcs. Thus, solar eclipses out number lunar eclipses by almost 5 to 3. In this argument, the Earth's penumbral shadow has been ignored since penumbral lunar eclipses are essentially unobservable.

In any one calendar year, there are at least two and as many as five solar eclipses. On the other hand, there can be no more than three lunar eclipses per year and it's quite possible to have none at all. Combining both solar and lunar eclipses, it's possible for one calendar year to contain a maximum of seven eclipses. However, they can only occur in the combinations of five solar and two lunar or four solar and three lunar. In either case, the solar eclipses must all be partial. As a point of interest, 1982 happened to be one of the rare years containing seven eclipses. What made it even more remarkable was the fact that all three lunar eclipses were total. This will not happen again until the year 2485 AD.

The previous discussion contradicts common experience because lunar eclipses are observed more frequently than solar eclipses. The conflict is resolved since solar eclipses are only visible from isolated regions of the Earth while lunar eclipses are visible from the entire night time hemisphere of our planet.

An examination of the geometry of the nodes yields further clues on the subject of eclipse recurrence. Since the Sun and Moon both subtend significant angles, neither one has to be exactly at the nodes for an eclipse to occur. In addition, an observer's position on the surface of the Earth introduces a sizable parallax of 2° in ecliptic latitude. These factors make a solar eclipse possible whenever the Sun is within 18.5° of a node. The Sun travels along the ecliptic at about 1° per day and requires about 37 days to cross through the eclipse zone centered on each node. New Moon occurs every 29 1/2 days and thus guarantees at least one eclipse during each of the Sun's node crossings.

The period during which the Sun is near a node is called an eclipse season and there are two eclipse seasons each year. If the line of nodes

were fixed in space, then eclipse seasons would occur six months apart and at the same time each year. Actually, the line of nodes slowly drifts westward at the rate of 19 degrees per year. As a result, eclipse seasons occur every 173.3 days. Two eclipse seasons constitute an eclipse year of 346.6 days. This is 18.6 days short of a solar year and is equal to the time required by the Sun to cross the same node twice.

In order to find a periodicity in the mechanics of solar eclipses, we must search for a commensurability between the synodic month and the eclipse year. Fortunately, 19 eclipse years are almost exactly equal to 223 synodic months; they differ by only 11 hours. The coincidence is all the more remarkable when compared to a period known as the anomalistic month. This is the time required for the Moon to pass from perigee to perigee and is approximately 27 1/2 days. The anomalistic month is important because the Moon's geocentric distance is the primary factor determining the annular or total nature of a solar eclipse. As unlikely as it may seem, 239 anomalistic months are also equal to 223 synodic months to within 6 hours.

This is the origin of the famous Saros cycle of 6585 1/3 days or 18 years, 11 days and 8 hours. Any two eclipses separated by one Saros cycle share very similar mechanical characteristics. They occur at the same node with the Moon at the same distance from Earth and at the same time of year. Because the Saros does not contain an integral number of days, its biggest drawback is that subsequent eclipses are visible from different parts of the globe. Although the 1/3 day displacement shifts the eclipse path 120° westward with each cycle, the series returns to the same geographic region every 3 Saroses or 56 years and 34 days.

A Saros series doesn't last indefinitely because the various periods are not perfectly commensurate with one another. In particular, 19 eclipse years are 1/2 day longer than the Saros. As a result, the node shifts eastward by about 0.5° with each cycle.

A typical Saros series begins when new Moon occurs about 18 degrees east of a node. If the first eclipse occurs at the Moon's decending node, the Moon's umbral shadow will pass 3500 km below the Earth and a partial eclipse will be visible from the south polar region. On the following return, the umbra will pass about 300 km closer to the Earth and a partial eclipse of slightly larger magnitude will result. After ten or eleven Saros cycles (about 200 years), the first central eclipse will occur near the south pole of the Earth. Over the course of the next 950 years, a central eclipse will occur at each Saros but will be displaced northward by an average of 300 km. Halfway through this period,

eclipses of long duration will occur near the equator. The last central eclipse of the series will occur near the north pole. The next ten eclipses will be partial with successively smaller magnitudes. Finally, the Saros series will end some 13 centuries after it began at the opposite pole. A typical series may be comprised of 70 to 80 eclipses, about 50 of which are central. If a Saros series begins near the ascending node, the first eclipse will be partial from the northern polar region and the previous sequence of events is reversed.

Since at least two solar eclipses occur every year, there are obviously many different Saros series in progress simultaneously. For instance, during the later half of the twentieth century, there are 41 individual series and 26 of them are producing central eclipses. As old series terminate, new ones are always beginning and take their places.

To illustrate, the total solar eclipses of 1925, 1943, 1961, 1979, 1997, 2015 and 2033 are all members of Saros 120 (Figure 3). The series began with a partial eclipse at the south pole in 915 AD. The 2033 event is the last central eclipse of the series. Note that the paths of the last four eclipses grow progressively broader as the umbral shadow cone passes closer to the limb of the Earth. The next eclipse in the series will be a partial eclipse in 2051. Saros 120 will end with a partial eclipse near the north pole in 2195.

MODERN ECLIPSE PREDICTION

In order to predict the general characteristics as well as the local circumstances for a solar eclipse, high accuracy ephemerides for both the Sun and the Moon are required. Conventional ephemerides tabulate the positions and distances of these bodies with respect to the Earth's center. However, the eclipse calculator is primarily interested in the position, dimensions and velocity of the Moon's shadow on the Earth's surface.

In 1824, the Prussian astronomer and mathematician Friedrich Bessel introduced a new theory for the prediction of eclipses. It was so successful that it remains today as the most powerful technique, even with the application of the digital computer. What Bessel did was to express the ephemerides of the Sun and Moon in terms of the Moon's shadow. This change in the frame of reference greatly simplifies the mathematics and geometry without any sacrifice in accuracy.

To define the Besselian elements of an eclipse, a plane is passed through the center of the Earth which is fixed perpendicular to axis of the lunar shadow. This is called the fundamental plane and on it is

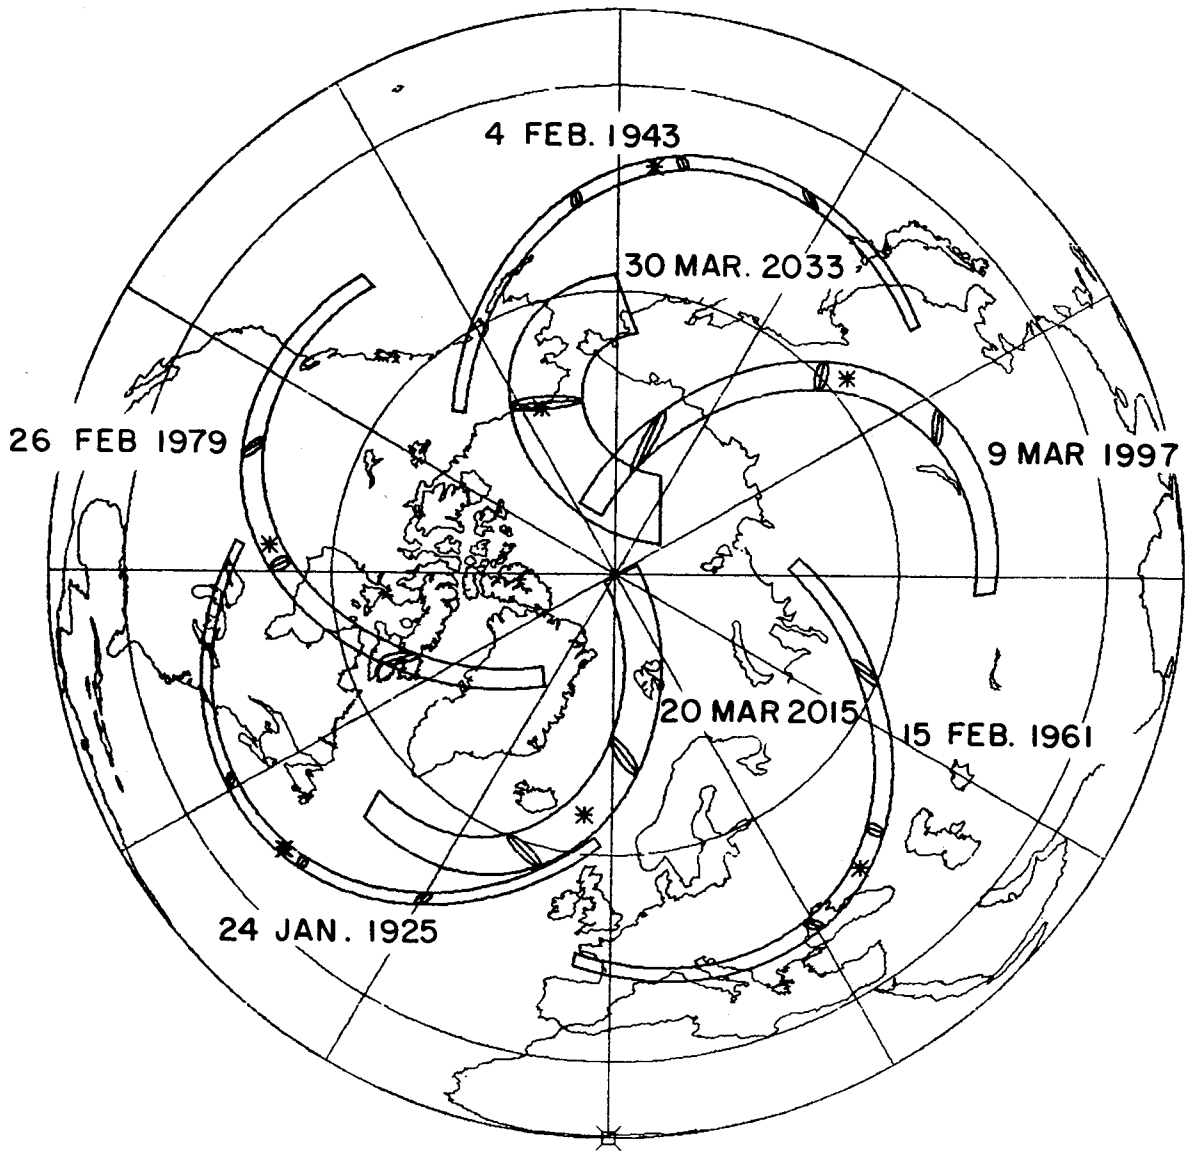

Figure 3

constructed an X-Y rectangular coordinate system with its origin at the geocenter. The axes of this system are oriented with north in the positive Y direction and east in the positive X direction. The Z axis is perpendicular to the fundamental plane and parallel to the shadow axis.

The X-Y coordinates of the shadow axis can now be expressed in units of the equatorial radius of the Earth. The radii of the penumbral and umbral shadows on the fundamental plane are also tabulated as L_1 and L_2, respectively. The direction of the shadow axis on the celestial sphere is defined by its declination 'd' and ephemeris hour angle 'μ'.

Finally, the angles which the penumbral and umbral shadow cones make with the shadow axis are expressed as f_1 and f_2, respectively. These eight parameters, tabulated at hourly intervals serve as the only input needed to characterize an eclipse. The details of actual eclipse calculations can be found in Chauvenet [1891] or the Explanatory Supplement [1974].

GEOMETRY OF THE UMBRAL SHADOW

The length of the Moon's cone-shaped umbral shadow is a function of the Moon's distance from the Sun. For any given eclipse, it can be determined by first calculating the half-angle 'f_2' which the umbral cone makes with its axis:

$$\sin f_2 = (\sin s_0 - k \sin \pi_0) / D_{sm}$$

where:
- s_0 = semi-diameter of Sun at mean distance (= 959.63")
- π_0 = horizontal parallax of Sun at mean distance (= 8.794")
- k = mean radius of Moon in Earth radii (= 0.272281)
- D_{sm} = distance between the Moon and Sun in Earth radii

The distance between the Moon and the Sun 'D_{sm}' is readily calculated as the difference in distance between the Moon and Earth 'D_m' and the distance between the Sun and the Earth 'D_s' as:

$$D_{sm} = D_s - D_m$$

$$D_m = 1 / \tan \pi_m$$

and

$$D_s = 1 / \tan \pi_s$$

where:
- D_m = distance of Moon from Earth in Earth radii
- D_s = distance of Sun from Earth in Earth radii

π_m = horizontal parallax of Moon (from Section 4)
π_s = horizontal parallax of Sun (from Section 4)

The length of the umbral shadow 'D_u' (in Earth radii) then follows as:

$$D_u = k \; / \; \tan f_2$$

An observer somewhere along the eclipse path can calculate their topocentric distance (in Earth radii) from the Moon 'D_t' as (approximately):

$$D_t = k \; / \; \tan (q \; s_s)$$

where: q = ratio of apparent diameters of the Moon and Sun as seen by the observer (from Section 3)
s_s = geocentric semi-diameter of Sun (from Section 4)

Then, the radius of the umbral shadow 'r_u' seen by an observer at topocentric distance 'D_t' is just:

$$r_u = k \; (D_u - D_t) \; / \; D_u$$

The local geometry of the umbral shadow at any one point along the eclipse path is rather complicated and changes rapidly. Ignoring the curvature of the Earth's surface, the shadow is elliptical with its major axis aligned along the azimuth of the Sun; the minor axis is equal to the actual diameter of the umbral cone at that point 'r_u'. The eccentricity 'e' of the shadow is related to the Sun's altitude 'A' by:

$$e = \sqrt{1 - \sin^2 A}$$

The major and minor semi-axes (in kilometers) of the umbral shadow ('a' and 'b', respectively) can also be used to define the eccentricity as:

$$e = \sqrt{a^2 - b^2} \; / \; a$$

where: $b = r_e \; r_u$

$$a = b \; / \; \sin A$$

and r_e = equatorial radius of Earth (= 6378.388 km)

Unfortunately, the azimuth of the shadow's path is independent of the parameters describing its shape. As a result, the width of the path of totality (or annularity) can take on any value between the major and minor axes' dimensions. In order to determine the relationship between the distance from the center line and the duration of totality, it is necessary to adopt a different frame of reference which will simplify this geometry.

Figure 4 represents the appearance of the umbral shadow, seen from the Moon as it sweeps over the Earth's surface. Neglecting the tiny irregularities in the Moon's limb profile, the shadow is quite circular. If the shadow is moving from the left to the right, the center line runs along diameter 'D' and totality lasts 'T' seconds. A hypothetical observer at point 'P' is clearly located perpendicular distances 'd' from the center line and 'h' from the path edge. Such information is readily obtained from a large scale map on which the path of totality has been plotted. As the shadow passes over the observer, he will lie on chord 'C'. The key question is : how long will totality last at point 'P' ?

From plane geometry, the length of chord 'C' is related to a circle's diameter 'D' and perpendicular distance 'd' by:

$$C = \sqrt{D^2 - 4d^2}$$

But the length of chord 'C' is directly proportional to the duration of totality at any point on the chord. Therefore, the duration of totality 't' at point 'P' is just:

$$t = T \cdot C / D = T \cdot \sqrt{D^2 - 4d^2} / D \text{ seconds}$$

where 'D' is the width of the path, 'd' is the distance of the observer from the center line and 'T' is the duration on the center line.

Expressing the duration of totality as a function of distance from the path edge, the relation for chord 'C' becomes:

$$C = \sqrt{4h(D-h)}$$

and the duration of totality 't' is:

$$t = T \cdot C / D = T \cdot \sqrt{4h(D-h)} / D \text{ seconds}$$

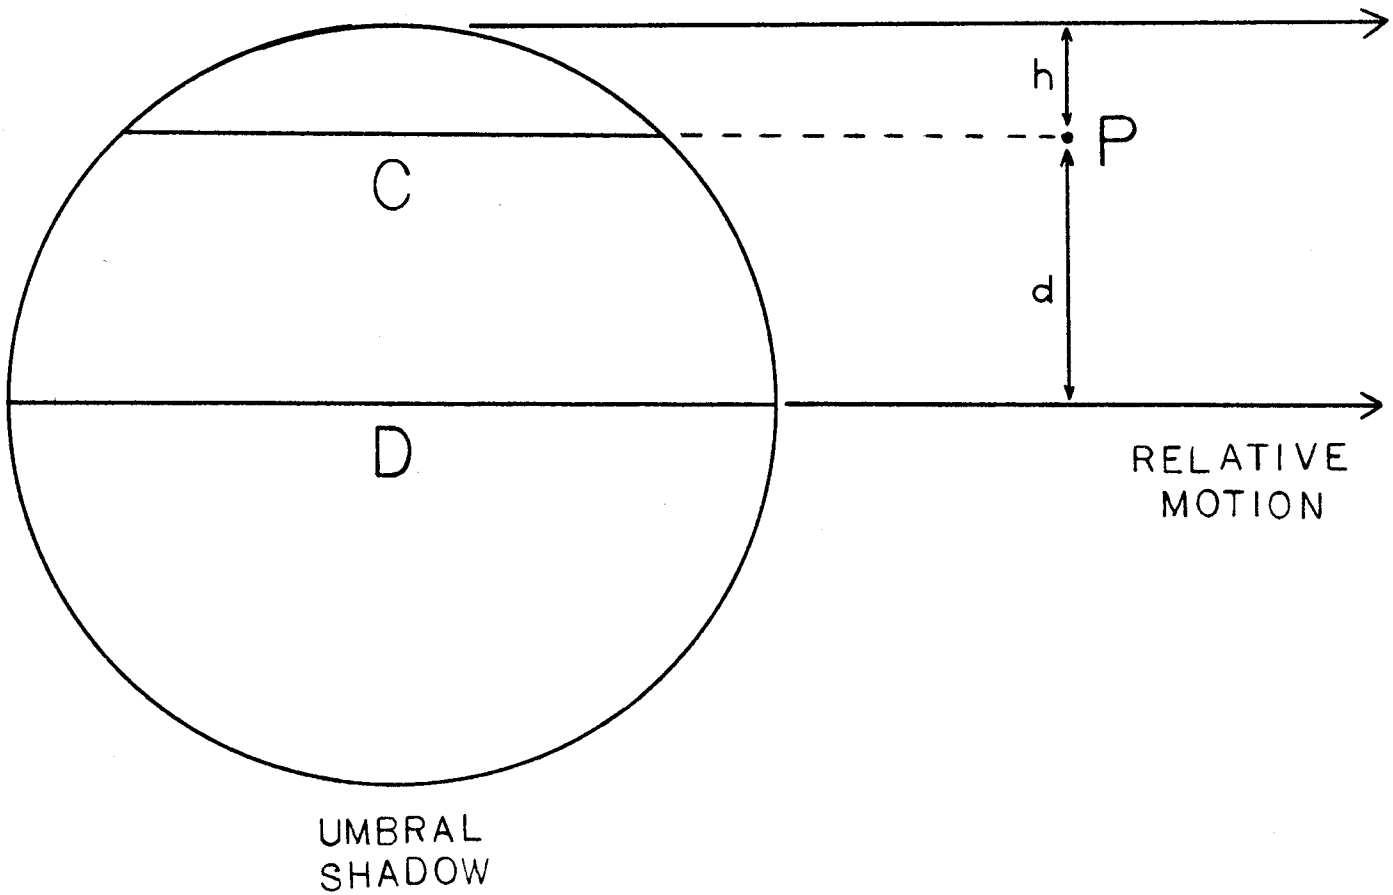

Figure 4

It should be pointed out that observers within 5 to 10 kilometers of the path edge must consider the effects of the lunar limb profile in determining the duration of totality.

TIME DETERMINATION

The measurement of time is of fundamental importance to all branches of science, but to none more so than astronomy. In fact, astronomy was born through man's first attempts to measure the passage of time by observing the motions of the Sun and the Moon. It should come as no surprise then, that time reckoning remains intricately entwined with astronomy even today. However, the Sun's apparent motion no longer plays the pivotal role as the ultimate temporal yardstick. It's been known for thousands of years that the length of the solar day is not constant but varies with an annual cycle. What was not known before Kepler's time was that the Earth's elliptical orbit about the Sun, coupled with the inclination in the planet's axis were responsible for the periodic variations.

Mean Solar Time can be conceptualized as time kept by a fictitious or mean Sun which moves eastward along the celestial equator at the average rate of the true Sun. Greenwich Mean Time (GMT) or Universal Time (UT) is simply Mean Solar Time as measured from Greenwich, England and was used in navigation and surveying for hundreds of years. Unfortunately, this too has fallen by the wayside because the Earth does not turn on its axis at a uniform and constant rate. As the Earth spins, a tidal friction is imposed on it through the gravitational interaction with the Moon and, to a lesser extent, the Sun. This secular acceleration gradually transfers angular momentum from the Earth to the Moon. As the Earth loses energy and slows down, the Moon gains this energy and its distance from the Earth increases. In fact, the Moon's distance will eventually increase to the point where its angular diameter is always smaller than the Sun's and total solar eclipses will no longer be possible. Although still in its infancy, the technique of lunar laser ranging has shown that the Moon's average distance from the Earth is increasing by about four centimeters per year. At this rate, total solar eclipses will continue to occur for the next 750 million years.

It should be pointed out that the secular acceleration of the Moon is very poorly known and may not be constant. Careful records for its derivation only go back as far as 100 years or so. Before then, spurious and often incomplete eclipse observations from medieval and ancient manuscripts comprise the data base. In any case, the current value

implies an increase in the length of the day by about 0.001 seconds per century. Such a trivially small amount may seem insignificant, but it has very measurable cummulative effects. In one century, the Earth loses 45 seconds, while in one millennium, the planet is one and a quarter hours "behind schedule".

The Earth's rotation on its axis is also subject to short term fluctuations for periods of up to several decades. It is believed that these fluctuations may be due to fluid motions in the Earth's core which interact with and disturb the rotation of the mantle. However, climatological changes and variations in sea-level may also play a significant role since they should alter the Earth's moment of inertia. Whatever the mechanism is, it is clear that its effects cannot be predicted with the current state of knowledge.

A better standard than diurnal rotation for the absolute measurement of time is the use of solar system dynamics. The orbital motions of the planets and of the Moon are predictable to very high accuracy and are directly verifiable through observations. The resulting time is referred to as Ephemeris Time (ET).

In 1957, the International Astronomical Union adopted Ephemeris Time as the standard and defined the ephemeris second as 1/31,556,925.9747 of the tropical year 1900 at January 0 at 12 hours Universal Time. The difference between Ephemeris Time and Universal Time (delta T or ΔT) is obtained through observations of the Moon. The Moon's position is predicted in terms of Ephemeris Time but it's observed with respect to Universal Time. Between 1900 and 1980, the slowing of the Earth's rotation on its axis had caused Universal Time to lag 50.54 seconds (= delta T) behind Ephemeris Time.

Ephemeris Time remained the basis of all time measurements until 1984. With the technological development of the atomic clock, a method of time measurement became available which has a permanence and stability unmatched by even celestial mechanics. The atomic or SI (for Systeme International) second is defined as 9,192,631,770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of the Cesium 133 atom. The SI second was carefully chosen to agree as closely as possible to the ephemeris second. In 1984, the SI second was adopted as the newest time standard and Terrestrial Dynamical Time (TDT) replaced Ephemeris Time. For consistency, the time scale for Terrestrial Dynamical Time was chosen to agree with 1984 Ephemeris Time.

Solar eclipse predictions are now based on Terrestrial Dynamical Time but the position of the central eclipse path still depends on

Universal Time. Unfortunately, it's impossible to predict how delta T (i.e.: TDT-UT) will vary in the future. At best, the current trends can be extrapolated but the resulting values of delta T will inevitably diverge from actual observations. As such observations become available, corrections to the eclipse path longitudes can be calculated as follows:

$$\text{Shift (in degrees)} = 0.00417807 * (\Delta T1 - \Delta T2)$$

where: $\Delta T1$ = table value of delta T (in seconds)
$\Delta T2$ = true or observed delta T (in seconds).

This shift is added to the tabulated path longitudes to calculate the correct longitudes of the central path. Changes in the value of delta T have no effect on the tabulated latitudes.

15. Supplementary Notes

16. Abstract

A complete catalog is presented, listing the general characteristics of every solar eclipse from 1901 through 2100. To compliment this catalog, a detailed set of cylindrical projection world maps show the umbral paths of every solar eclipse over the 200 year interval. Focusing in on the next 50 years, accurate geodetic path coordinates and local circumstances for the 71 central eclipses from 1987 through 2035 are tabulated. Finally, the geodetic paths of the umbral and penumbral shadows of all 109 solar eclipses in this period are plotted on orthographic projection maps of Earth.

Appendices are included which discuss eclipse geometry, eclipse frequency and occurrence, modern eclipse prediction and time determination. Finally, code for a simple Fortran program is given to predict the occurrence and characteristics of solar eclipses.
